CIVITAS indicators

Transport pollutant emissions (ENV_PL_PE)

DOMAIN

Transport	**Environment**	Energy	Society	Economy

TOPIC	**Pollution**	
IMPACT	**Transport pollutant emissions** *Reducing the pollutant emissions of urban mobility*	**ENV_PL**

Category

Key indicator	Supplementary indicator	State indicator

CONTEXT AND RELEVANCE

Transport activity is a relevant source of pollution. A significant share of transport activity occurs in the urban context. Reducing the pollutant emissions generated by urban mobility is a significant contribution to sustainability.

This indicator is an estimation of the amount of urban mobility pollutant emissions. **It is a relevant indicator when the policy action is aimed at reducing the impact of urban mobility and transport on the urban air quality. A successful action is reflected in a LOWER value of the indicator.**

DESCRIPTION

The indicator is not a single number but **a vector** of the quantity of emissions, expressed in **tonnes/year**, for three pollutants: **Particulate Matter (PM), Nitrogen Oxides (NOx), Volatile Organic Compounds (VOC)**.

METHOD OF CALCULATION AND INPUTS

There are two methods for the calculation of the indicator. One method is extracting the value of emissions from an urban transport model. **If a city transport model exists** and provides an estimation of the pollutant emissions from all relevant modes of transport, this method has zero complexity. Furthermore, assuming that the model is reliable, results have a good level of significance. However, **if an urban model does not exist**, its complexity becomes high because building an urban transport model is not straightforward.

An alternative method is estimating pollutant emissions building on energy use for urban transport activity. The energy use should be available by fuel type. Energy use by fuel type can be obtained from different sources. One option is collecting energy supplied at refuelling stations and energy operators (see factsheet related to the indicator ENG_EF_ED1). Another option is estimating energy used building on vehicle fleets, mileage and use factors (see factsheet related to the indicator ENG_EF_ED3). A third option is extracting energy consumption from an urban transport model, if there is a city transport model providing energy consumption by fuel type (but not pollutant emissions, otherwise the first method can be applied). This method is not very complex; more complex than extracting emissions from an existing model, but definitely less complex than building an urban transport model to estimate emissions. Its level of significance depends on the completeness of the data on energy use. On average, method 2 is probably less significant than method 1.

Whatever the method used, the pollutant emissions should be computed exogenously and then coded in the supporting tool.

METHOD 1	METHOD 2
Pollutant emissions drawn from an urban transport model	**Pollutant emissions estimated from energy consumption by fuel type**
Complexity 	Complexity 
Significance 	Significance 

The estimation process is explained below for both methods.

Method 1

Pollutant emissions drawn from an urban transport model

Significance: **0.75** 

The following information is needed to compute the indicator:

a) **The volume of transport emissions of PM, NOx and VOC** in the period covered by the urban transport model.

Urban transport models can refer to different periods e.g., one peak hour, two peak hours, one peak and one off-peak hour, an average day and so on. Whatever is the period, the emissions provided by the model are the input required, which need to be translated in an annual value (see Method of Calculation). If the model already provides annual emissions, this information is already the indicator.

The experiment would result in a modification of the amount of emissions estimated by the model.

METHOD OF CALCULATION

The indicator should be computed **exogenously** according to the following steps:

- **Identification of the period covered by the transport model** (e.g., one peak hour, two peak hours, whole day, etc.)**.**
- **Identification of the share of daily of traffic covered by the transport model.** The share of traffic covered by the transport model depends on the modelled period and on the distribution of transport activity in the 24 hours. This distribution is different in different contexts. If a transport model exists, this parameter is usually known. If not, 10% is a reasonable value for a morning peak hour.
- **Definition of the factor to extrapolate from day to year.** Most of the models refer to an average working day. If so, this term depends on the number of working days per year. Again, if a model exists, this parameter is usually known. If not, 270 working days/year can be considered.

- **Calculation of the extrapolation factor**. The extrapolation factor should be the product of two terms above (see the following equations).

- **Application of the extrapolation factor and estimation of the indicator** (see the following equations).

EQUATIONS

The extrapolation factor should be computed as:

$$\boldsymbol{ExtpFact} = \frac{\mathbf{1}}{\boldsymbol{DayModShr}} * \boldsymbol{DaytoYear}$$

Where:

$DayModShr$ = share of daily of traffic covered by the transport model

$DaytoYear$ = Factor to extrapolate from day to year

Example, if the model covers two hours and $DayModShr$ = 16% of daily traffic, and 270 working days ($DaytoYear$) are considered, the extrapolation factor is:

$$ExtpFact = \frac{1}{0.16} * 270 = 1687$$

The value of the indicator is then computed as:

$$\boldsymbol{{}^{p}PollEmis} = \boldsymbol{{}^{p}ModPollEm} * \boldsymbol{ExtpFact}$$

Where:

${}^{p}ModPollEm$ = Emissions of pollutant *p*, related to the modelled period, extracted from the model (**tonnes**).

Method 2

Pollutant emissions estimated from energy consumption by fuel type

Significance: **0.50**

The following information is needed to compute the indicator:

a) **The amount of energy used in a given period** for each relevant fuel type. The fuel types to be considered are the followings:
   - **Gasoline**
   - **Diesel**
   - **LPG**
   - **CNG**
   - **Electricity**

   If some of these fuel types are not relevant in the experiment area, they are not considered.

b) **The emission factors** of each fuel type. This element consists of a set of values based on chemical characteristics of the fuels and on technical characteristics of the

vehicles. The following average values can be used unless more specific values can be available in the pilot site:

	PM	*NOx*	*VOC*	*Unit*
Gasoline	0.063	6.517	0.294	g/l
Diesel	0.737	9.522	0.476	g/l
LPG	0.022	0.078	0.118	g/l
CNG	0.027	0.088	0.000	g/kg
Electricity	0.006	0.000	0.000	g/kWh

The experiment would result in a modification of the amount of energy used. The emission factor of each fuel is fixed.

METHOD OF CALCULATION

The indicator should be computed **exogenously** according to the following steps:

- **Identification of the existing refuelling stations.**
- **Definition of a sample of refuelling stations** if their total number is too large for collecting data from all of them.
- **Collection of data from the refuelling stations**
- **Estimation of total amount of fuel supplied** in case the data is collected from a sample of stations (see equation below).
- **Estimation of the pollutant emissions** (see equation below)

EQUATIONS

If the amount of fuel is collected from a sample of refuelling stations, the total value of energy supplied for these two fuel types should be estimated according to the following equation:

$$EngSupl^{e} = \frac{\sum_{s} EngSupl_{s}^{e}}{n} * N$$

Where:

$EngSupl_{s}^{e}$ = Amount of fuel type *e* supplied by sampled refuelling station *s* in the monitored four weeks

n = Number of sampled refuelling stations

N = Total number of refuelling stations supplying fuel type *e* in the urban area

The pollutant emissions can be obtained by simply applying the average emissions factors to the total value of energy by fuel type:

$$\boldsymbol{PollEmiss} = \sum_{\boldsymbol{e}} (\boldsymbol{EngSupl^{e}} * \boldsymbol{EmissFact^{e}})$$

Where:

	$EmissFact^{e}$ = the average emission factor of fuel type *e*

ALTERNATIVE INDICATORS

This indicator refers to pollutant emissions in a certain period. Even if emissions affect the air quality, which is however better measured by the concentration of pollutants. The same amount of emissions can result in different concentrations depending on several conditions such as weather (e.g., given a certain level of emissions, air quality will be better in a windy context). The indicator ENV_PL_AQ2 refers to the air quality and can be used in alternative to this indicator. The disadvantage of the alternative indicator is that observed concentrations used for its computation is not necessarily available in all pilot areas and, even when available, they can make reference to a limited number of spots only. Furthermore, given that concentrations are affected by the weather, assessing whether a modification of the alternative indicator depends on the pilot or not can be impossible.
